

Problem:

Find the amount of revenue that can be collected in tourism by inputting data from a csv file

Objective:

Easily predict the revenue collection of tourism.

Dataset:

This dataset has 7 columns and 5988 rows. It has details about Location, Country, Category, Visites, Rating, Revenue, Accomodation. Here our target variable is Revenue.

Model used

Multiple regression.

This is used because the the target column was depended on more than 1 columns.

Model evaluation

Error = 0.9861215865...

Done using root mean sq error

and the intercept and coeff were obtained.

Conclusion

With the help of this ML code now we can find the revenue of the tourism if the required input data is given.

Reflection

From this project I learned ~~how~~ how to combine the different aspects in ML taught into a single project. Most challenging thing was to debug the error due to the code mo was higher and preprocessing was also little time consuming. But lessons of EDA, scaling, training

and combining everything was very good to learn. I also got to know ML codes really work while finding my mistakes.

My source of the dataset was kaggle.com.
